Video Coding On Multi-Core Graphics Processors

Ngai-Man Cheung, Xiaopeng Fan, Oscar C. Au, Man-Cheung Kung

Abstract— In this article, we investigate using multi-core graphics processing units (GPUs) for video encoding and decoding. After an overview of video coding and GPUs, we review some previous work on structuring video coding modules so that the massive parallel processing capability of GPUs can be harnessed. We also review previous work on partitioning the video decoding flow between the central processing unit (CPU) and GPU. After that, we discuss in detail a GPU based fast motion estimation to illustrate some design considerations in using GPUs for video coding, and the tradeoff between speedup and rate-distortion performance. Our results highlight the importance to expose as much data parallelism as possible in designing algorithms for GPUs.

I. INTRODUCTION

Today, video coding [1]–[5] has become the central technology in a wide range of applications. Some of these include digital TV, DVD, Internet streaming video, video conferencing, distance learning, and surveillance and security [6]. A variety of video coding standards and algorithms have been developed (e.g., H.264/AVC [5], VC-1 [7], MPEG-2 [8], AVS [9]) to address the requirements and operating characteristics of different applications. With the prevalent applications of video coding technologies, it is important to investigate efficient implementation of video coding systems on different computing platforms and processors [10], [11].

Recently, Graphics Processing Units (GPUs) have emerged as co-processing units for Central Processing Units (CPUs) to accelerate various numerical and signal processing applications [10], [12]–[14]. Modern GPUs may consist of hundreds of highly decoupled processing cores capable of achieving immense parallel computing performance. For example, the NVIDIA GeForce 8800 GTS processor has 96 individual *stream processors* each running at 1.2 GHz [15]. The stream processors can be grouped together to perform Single Instruction Multiple Data (SIMD) operations suitable for arithmetic intensive applications. With the advances in GPU programing tools such as thread computing and C programming interface [16], [17], GPUs can be efficiently utilized to perform a variety of processing tasks in addition to conventional vertex and pixel operations.

With many personal computers (PCs) or game consoles equipped with multi-core GPUs capable of performing general purpose computing, it is important to study how GPU can be utilized to assist the main CPU in computation-intensive tasks such as video compression/decompression [18]. In fact, as high-definition (HD) contents are getting popular, video coding would require more and more computing power. Therefore, leveraging the computing power of GPU could be a cost-effective approach to meet the requirements of these applications. Note that with dozens of available video coding standards (H.264, MPEG-2, AVS, VC-1, WMV, DivX) it is advantage to pursue a flexible solution based on software.

Focusing on software-based video coding applications running on PCs or game consoles equipped with both CPUs and GPUs, this article investigates how GPUs can be utilized to accelerate video encoding/decoding. Recent work has proposed to apply multi-core GPU/CPU for various video/image processing applications. Table I summarizes some of them. In this article, we survey prior work on video encoding and decoding to illustrate the challenges and advantages of GPU implementation. Specifically, we discuss previous work on GPU-based motion estimation, motion compensation and intra prediction. Our focus is on how the algorithms can be designed to harness the massive parallel processing capability of GPU. In addition, we discuss previous work on partitioning the decoding flow between CPU and GPU (For completeness, we also report the speedup results in previous work. However, since the GPU/multi-core software/hardware technologies have evolved dramatically over the last few years, some of the results could be outdated). After that, we investigate a GPU based fast motion estimation. We discuss some strategy to break dependency between different data units, and examine the tradeoff between speedup and coding efficiency.

The rest of this article is organized as follows. We first provide an overview of the state of the art in video coding and GPUs. We also discuss the challenges to use GPUs to assist video coding. Then, we review previous work on GPUaccelerated video coding. After that, we study GPU based fast motion estimation. Finally, this article ends with concluding remarks.

II. BACKGROUND

A. Video coding

The latest video coding standards have achieved state-ofthe-art coding performance. For example, H.264/AVC, which is the latest international video coding standard approved by ITU-T and ISO/IEC, typically requires 60% or less of the bit rate compared to previous standards in order to achieve the same reconstruction quality [5]. Other advanced video coding algorithms, such as AVS-Video developed by the Audio and Video Coding Standard Working Group of China [9], or VC-1 initially developed by Microsoft [7], have also achieved competitive compression performance. In the following we provide an overview on H.264 video coding standard.

H.264 video coding standard is designed based on the block-based hybrid video coding approach [2], [5], which has

TABLE I

VIDEO AND IMAGE PROCESSING APPLICATIONS ON MULTI-CORE PROCESSORS.

Applications	Examples
Video encoding	Motion estimation [19]–[23], intra prediction [24]–[27], transform [28]
Video decoding	Motion compensation [10], [29], decoder design [10], [30]–[32]
High dynamic range (HDR) images	Texture compression [33]
Video watermarking	Real-time video watermarking system [14]
Signal processing kernels	Matrix and vector computations [12], fast Fourier transform and convolution [13]
Image analysis	Hough transform [34], Radon transform [35], [36], chirplet transform [35], feature extraction [37]

been used since earlier video coding standards. The coding algorithm exploits spatial correlation between neighboring pixels of the same picture. In addition, it also exploits temporal correlation between neighboring pictures in the input video sequence to achieve compression. Figure 1 depicts the encoder block diagram. The input picture is partitioned into different blocks, and each block may undergo intra prediction using neighboring reconstructed pixels in the same frame as predictor. H.264 supports intra prediction block sizes of 16×16 , 8×8 and 4×4 , and allows different ways to construct the prediction samples from the adjacent reconstructed pixels. Alternatively, the input block may undergo inter prediction using the reconstructed blocks in the reference frames as predictor. Inter prediction can be based on partition size of $16 \times 16, 16 \times 8, 8 \times 16, 8 \times 8, 8 \times 4, 4 \times 8, \text{ or } 4 \times 4$. Displacement between the current block and the reference block can be up to quarter-pel accuracy and is signaled by the motion vector and the reference picture index [2].

The prediction residue signal from intra prediction or inter prediction would then undergo transformation to de-correlate the data. In H.264, a 4×4 separable integer transform is used, which is similar to 4×4 DCT but avoids the mismatch between forward and inverse transform. Then, the transform coefficients would be scalar quantized and zig-zag scanned. The Context-Adaptive Variable Length Coding (CAVLC) may then be employed to entropy code the scanned transform coefficients. CAVLC is an adaptive coding scheme, and it may switch between different codeword tables during encoding depending on the values of the already-coded elements. Alternatively, the transform coefficients may be coded by Context-Adaptive Binary Arithmetic Coding (CABAC). To mitigate blocking artifacts, an adaptive in-loop deblocking filter would be applied to the reconstruction from the feedback loop.

B. Graphics processing units (GPUs)

Originally designed as specialized hardware for 3D graphics, GPUs have recently emerged as co-processing units to accelerate arithmetic intensive applications in PCs or game consoles. A key feature of modern GPUs is that they offer massive parallel computation capability through hundreds of highly decoupled processing cores [38]. For example, NVIDIA GeForce 8800 GTS processor consists of 96 stream processors each running at 1.2 GHz [15].

The design philosophy of GPUs is quite different from that of general-purpose CPUs. Throughout the years, GPUs have been designed with an objective to support the massive number of calculations and huge amount of data transfer required in advanced video games [38], [39]. In addition, they need

Fig. 1. H.264/AVC encoding algorithm [5].

to meet the stringent cost requirement of consumer applications. Therefore, GPUs have become very cost-effective for arithmetic computation. Furthermore, the peak computation capability of GPUs is increasing at a faster pace than generalpurpose CPUs (Figure 2).

Besides arithmetic computation capability, there are other fundamental differences between CPUs and GPUs. First, in order to address a wide range of applications, general purpose CPUs would use many transistors to implement sophisticated control hardware that can support some advanced control functions such as branch prediction [40]. On the contrary, GPUs would instead devote chip area to arithmetic computation. As a consequence, GPUs may not perform well for programs with many conditional statements. Second, CPUs use a lot of chip area to implement cache memory in order to reduce instruction and data access latencies. GPUs, on the other hand, use much simpler memory models, but rely on the high degree of parallelism in an application to hide the memory access latency. Thus, it is central to expose a large amount of data parallelism in GPU programs.

C. GPU-assisted video coding: Challenges

Following from the previous discussion, it is clear that only certain types of computation are suitable for GPU execution. In particular, to fully harness the computational power in GPU, one would need to design the algorithm to utilize the massive number of processing cores in parallel. As an example, a good application may run up to thousands of threads simultaneously on a high-end GPU so as to keep all the processing cores

working continuously [38]. Therefore, one of the main challenges to utilize GPU for video coding is how to structure a certain module to expose as much data parallelism as possible. Note that this may not be trivial for some video coding modules since dependency may exist between different data units in the computation, as pointed out by previous work [22], [24], [25], [27]. Moreover, flow control instructions (if, switch, do, for, while) can significantly degrade the performance of GPU execution, since such instructions may cause different threads to follow different execution paths and the execution would need to be serialized [39]. Therefore, using GPUs for entropy coding such as CAVLC could be challenging. Furthermore, an implementation should try to avoid as much as possible off-chip data access, which may incur considerable latency (recall that GPU is not optimized for memory access latency). For example, some GPUs may require up to 400 to 600 cycles latency for off-chip memory access (while they can perform single-precision floating-point multiply-add in a single cycle in each core) [39]. Note that it is possible to hide such memory access latency if there are enough independent arithmetic computations. Therefore, if possible, a video coding module should be implemented with high arithmetic intensity (which is defined as the number of mathematical operations per memory access operation). In some situation, it could be more efficient to re-calculate some variables rather than loading them from the off-chip memory.

Fig. 2. Peak computation capability of GPUs and CPUs [39], [41].

III. PREVIOUS WORK

In this section we review previous work on applying GPUs for video coding. Previous work has proposed to utilize GPUs to undertake motion estimation [19]–[22], intra prediction [24]–[27] and motion compensation [10], [29]. Note that motion estimation, intra prediction and motion compensation are some of the most computation-intensive modules in inter-frame encoding, intra-frame encoding and decoding respectively. Therefore, it is important to understand how these modules can be efficiently implemented on GPUs. In addition to these modules, GPU based discrete cosine transform (DCT) has been discussed in [28]. There seems to be no previous work on GPU based deblocking filter. Since deblocking filter involves some conditional statements to determine the strength of the filter at each block boundary, some study may be necessary to determine its performance on GPUs.

A. Motion estimation on GPUs

Motion estimation (ME) is one of the most computationintensive modules in video encoding, and there has been a lot of interest to offload it to GPUs to improve the overall encoding performance. Earlier work in this area focuses on ME algorithms where sum of absolute differences (SAD) is used in block matching to determine the best candidate. SAD computation can be easily parallelized as each individual pixel in the current block is compared independently with the corresponding pixel in the candidate reference block. Note that SAD-based ME is commonly used in MPEG-1/2 and H.263.

More recent video encoding algorithms, on the other hand, may employ rate-distortion (RD) optimized ME that considers both the rate and distortion in selecting the best candidate. For example, one common metric is the weighted sum of the SAD (between the current block and the candidate block) and the encoding rate of the motion vectors (MVs). In H.264 standard, predictive coding is used to encode the MV of the current block, and the predictor is the median of the MVs in the adjacent left, top and top-right blocks. Therefore, in RD-optimized ME, the MVs of the neighboring blocks would need to be first determined. Then, based on the median of the neighboring MVs, encoding rate of the current MV can be determined and the cost of the current block can be computed in the block matching. Such dependency makes it difficult to utilize GPUs for RD-optimized ME. We will discuss example designs to address this issue.

1) GPU-based motion estimation based on loop unrolling: In order to increase the degree of parallelism, [20] proposed to unroll the computation loop in SAD-based full search ME. The ME computation loop is shown in Figure 3, and loop unrolling is possible since there is no dependency between individual macroblocks (MBs) when SAD is used as metric for matching. Due to resource constraint in earlier GPUs, the algorithm in [20] needs to be partitioned into two separate passes so that the GPU memory can accommodate the instructions. The experiments in [20] compared full search ME on an INTEL Pentium 4 3.0GHz CPU and on a NVIDIA GeForce 6800 GT GPU, and the results suggest the GPU-based ME can achieve up to two times and 14 times of speed-up for integer-pel and half-pel ME respectively. The considerable improvement in the half-pel ME is due to the fact that [20] utilizes the built-in hardware support in GPU for interpolation.

Note that with loop unrolling it is possible to schedule a massive number of parallel threads (subject to device's constraint). Consider an example to assign one thread to compute one SAD between a MB and a candidate block in the search window. Then, in the case of full search, the number of independent threads could be as large as the number of MBs times the number of candidate blocks per MB (search window size). For HD 720P videos (1280×720 , 3600 macroblocks per frame), and a search range of 64 (129×129 search window size), the number of threads could be as many as $3600 \times 129 \times 129 = 59907600$.

Although full search is highly parallel, it may have only little practical interest because of the prohibitive computational requirement, especially for HD video contents. Moreover, when MBs are processed independently and MVs are computed concurrently in different threads, it becomes difficult to use motion vector prediction, where MVs of neighboring blocks are used to initialize the search of current MB, and this may affect ME performance when the search window is small. In Section IV we will discuss GPU implementation of fast ME, which can in general achieve comparable coding performance as full search with a much smaller number of computations [42].

Fig. 3. Pseudo code of conventional integer-pel ME based on SAD.

2) GPU-based motion estimation based on rearranging the encoding order: Due to the dependency between adjacent blocks as discussed, RD-optimized ME commonly employed in recent video coding standards cannot be parallelized simply by loop unrolling. In [21], [22], rearrangement of the encoding order is proposed to increase the degree of parallelism. In these algorithms, instead of processing the blocks in the conventional raster-scan order, the blocks are processed along the diagonal direction to address the dependency issue. This is shown in Figure 4 for the case of 4×4 ME. In their proposed encoding order, at each iteration, the ME will process all the blocks of which the neighboring blocks (left, top and topright) have been processed. That is, the ME processes at each iteration all the blocks of which neighboring MVs have been computed and median predictors are available. By processing blocks along the diagonal direction the proposed rearrangement can substantially increase the degree of parallelism. For example, [22] reported that the maximum degree of parallelism can be up to 44, 160 and 240 for CIF, 720p and 1080p video respectively. Note that for each 4×4 block, individual search points in the search window can be examined in parallel (in the cases of full search or some fast search with regular sampling of search window). Therefore, with block-level parallelism of 240 (i.e., 240 4×4 blocks in the current frame can be processed in parallel) and a search range of 64 $(129 \times 129$ search window size), $240 \times 129 \times 129 = 3993840$ independent threads can be launched simultaneously in principle. Pixel level parallelism can also be implemented, e.g., by decomposing the SAD calculation into several threads. The results in [22] suggest that over 40 times of speed-up can be achieved in a system with an INTEL Pentium 4 3.2GHz CPU and a NVIDIA GeForce 8800 GTS graphics processor. Note that Pentium 4 CPUs are relatively slow compared with more recent CPUs. Also the program code on Pentium might not have been well optimized. Thus the reported speed-ups in [22] could be higher than those w.r.t. more efficient CPU implementation. Nonetheless, the results still suggest RD-optimized ME can be implemented efficiently on GPU.

Fig. 4. Block encoding order proposed in [22] for H.264 4×4 RD-optimized ME. Each square represents a 4×4 block. Blocks with the same number (e.g., 5a, 5b, 5c) are to be processed in parallel.

B. Rate-distortion optimized intra mode decision on GPUs

Recent video encoding algorithms use RD optimized intra mode selections to determine the optimal intra prediction direction. In these methods, the encoder would compute the Lagrangian costs of all the candidate prediction modes and select the prediction mode which minimizes the cost. The Lagrangian cost can be the weighted sum of the sum of square differences (SSD) between the original and reconstructed block and the encoding rate for header and quantized residue block. To calculate the cost for a candidate mode, it may involve computing the intra prediction residue, inverse quantization and inverse transformation, and entropy coding of the quantized transform coefficients. Therefore, the computational complexity of RD optimized intra mode selection could be very significant [43]–[45].

Achieving massive parallelization of RD optimized intra decision can be challenging. It is because, in intra prediction, the *reconstructed* pixels of the neighboring blocks are used to compute the reference samples. Therefore, the intra prediction modes of the neighboring blocks would need to be first determined, and these blocks would be encoded and reconstructed accordingly. Then, different candidate modes of the current block can be evaluated based on the reconstructed pixels in the neighboring blocks. Such dependency hinders the parallelization of RD optimized intra decision for GPU implementation.

To address the dependency issue, previous work has proposed different strategies to modify the block processing order [26], [27], [46]. In particular, [27] analyzes the dependency constraint and proposes to process the blocks following a greedy strategy: in each iteration, the encoder would process all the blocks of which parent blocks have been encoded (In the dependency graph, Block A is the parent block of block B if block B requires the reconstructed pixels from block A under various candidate prediction modes). Also, in the greedy strategy, a video block will be scheduled for processing immediately after all its parent blocks have been processed. Figure 5 depicts the dependency constraint in H.264 4×4 intra prediction and the scheduling under the greedy strategy. [27] argues that the greedy strategy is optimal for H.264 and AVS encoding: under the specific constraints imposed by H.264/AVS, and among all encoding orders obeying the constraints, the greedy-based encoding order requires the minimum number of iterations to process all the blocks. Simulation results suggest that, using the greedy strategy, GPU-based intra mode decision can achieve about up to two times speedup in a system with an INTEL Pentium 4 3.2GHz CPU and a NVIDIA GeForce 8800 GTS graphics processor (Table II). According to [27], the average parallelism is about 127 for 1080P videos, and a two times speedup seems to agree with our results in Section IV for fast motion estimation.

Fig. 5. (a) Notations for dependency graph: each block corresponds to a 4×4 block. (b) Dependency graph when processing an image frame in H.264 RD-optimized intra mode selection. Each node represents a 4×4 block (See Figure 5(a) for notations). A directed edge going from block A (parent node) to block B (child node) indicates that block B requires the reconstructed pixels from block A to determine the RD costs of various candidate prediction modes. The graph is processed following the greedy strategy proposed in [27], and the figure shows the iteration at which each block is processed.

C. Motion compensation on GPUs

GPU-based motion compensation (MC) has been proposed by [10] and [29] for Windows Media Video (WMV) and H.264 video decoding respectively. Motion compensation requires a lot of computations, since video coding standards allow motion vectors to point to sub-pixel locations (e.g., half-pel or quarterpel) and intensive pixel interpolation would be necessary to generate the prediction samples for motion displacements with fractional values. For example, in H.264, a half-pel sample is generated from six other samples using a six-tap interpolation filter. And to generate a quarter-pel sample it may require an additional linear interpolation.

The work in [10] discusses techniques to address the overflow and rounding problem in interpolation arised in MC. Note that MC can be parallelized since each block can be processed independently using its motion vector information, and this is implemented by a pipeline of vertex/pixel shader procedures in [10]. In their GPU implementation, they use a multipass technique which handles the residuals and rounding control parameter in a separate pass to avoid overflow while preserving the precision. In addition, [10] discusses how different modules in video decoding can be partitioned between CPU and GPU, and how CPU computation can be maximally overlapped with GPU computation (this will be

further discussed). Simulation results suggest that, in a system with an INTEL Pentium III 667MHz GPU and a NVIDIA GeForce3 Ti200 GPU, by leveraging the GPU the system can achieve more than three times of speed-up, and it is possible to achieve real-time WMV (version 8) decoding of high-definition video of resolution up to 1280×720 [10].

D. Task partition between CPU and GPU

To obtain competitive system performance, CPU and GPU need to be considered together for encoding/decoding. Investigating the optimal partition of computation tasks between CPU and GPU, however, could be very involved, and it requires serious evaluation on many issues. For example:

- It is necessary to investigate how to allocate the tasks such that GPU computation can overlap with CPU computation as much as possible, thereby achieving maximal parallel processing.
- Since the bandwidth between GPU memory and main memory could be slow, it is important to investigate how to minimize the data transfer between main memory and GPU memory.
- It is also important to study and evaluate which modules in the encoding/decoding flow can be efficiently offloaded to GPU, while other would be executed on CPU.

Focusing on WMV decoding, [10] proposes a partition strategy where the whole feedback loop, including motion compensation and color space conversion (CSC), is offloaded to GPU. By doing so, they can avoid transferring the data back from GPU to CPU. Since read-backs from GPU memory to main memory could be slow due to common asymmetric implementation of the memory bus [10], such read-backs should be minimized. Figure 6 depicts the partition strategy. Note that while GPU is performing MC and CSC of frame n, CPU would be preforming variable-length decoding (VLD), inverse quantization (IQ) and inverse DCT (IDCT) of the frame n+1. Note also that intermediate memory buffer is used between CPU and GPU to absorb the jitters in CPU/GPU processing time. Simulation results in [10] suggest intermediate buffer size of four frames can considerably improve the overall decoding speed.

While [11] has discussed some issues (e.g., bandwidth requirement) on offloading motion estimation to GPU, there seems to be no prior work on rigorous investigation on how video encoding may be partitioned between CPU and GPU. We remark that GPU implementation of several important encoding modules (including motion estimation, intra-mode decision, motion compensation and transform) have been investigated in the past, while that of deblocking filter and entropy coding need further research.

Fig. 6. Task partitioning in WMV decoding proposed by [10].

IV. CASE STUDY: GPU BASED FAST MOTION ESTIMATION

To illustrate some design considerations in using GPUs for video coding, we discuss in detail in this section a GPU based fast ME (The GPU ME code was developed by the authors based on the H.264 JM 14.2 reference software). The focuses are on how to address the data dependency in the algorithm to harness the parallel processing capability of GPUs, and on how to trade-off the speedup with rate-distortion (RD) performance.

A. Fast motion estimation

Our GPU implementation of fast ME is based on *simplified unsymmetrical multi-hexagon search (smpUMHexagonS)* [42], which is one of the fast ME algorithms adopted by the H.264 JM reference software. We select smpUMHexagonS because it can achieve very good tradeoff between computational complexity and coding efficiency. For example, on a Pentium 4 CPU it was reported smpUMHexagonS can achieve up to 94% reduction in ME execution time with comparable RD efficiency, when compared with the fast full search in the JM software [42]. In addition, smpUMHexagonS is quite compact, so it could meet the memory constraint of GPU. In our implematation, all the GPU kernels that deal with integer-pel estimation have about 600 lines of code.

Figure 7 depicts the flow chart of smpUMHexagonS. For each macroblock, smpUMHexagonS computes the MVs for all the macroblock partitions $(16 \times 16, 16 \times 8, ..., 4 \times 4)$. MVs are selected by minimizing the Lagrangian cost $D + \lambda R$, where D is the SAD between the current block and the candidate, and R is the bit-rate to encode the MV. In smpUMHexagonS, computation reduction is achieved mainly by sampling the search space judiciously, using several techniques including motion vector prediction, different search patterns (cross, hexagon, diamond) and early termination. In particular, motion vectors from spatially adjacent blocks and from other macroblock partitions are used to initialize the search for the current partition. Notice that as depicted in Figure 7 smpUMHexagonS uses several tests to determine if the search (of the current partition) can be terminated based on the minimum cost computed so far. As a result, different macroblocks with different contents may undergo different processing paths (which is typical in many fast ME algorithms [47]), and this may affect the performance of the GPU implementation.

Fig. 7. Fast motion estimation using smpUMHexagonS [42]. The figure depicts the steps for integer-pel search for a macroblock partition.

B. GPU implementation using tiling

To utilize the parallelism in GPU, we partition the current frame into multiple tiles, and each tile contains K (height) $\times L$ (width) MBs. For example, Figure 8 depicts the case with K = 1, L = 4. Each tile is processed by a single GPU thread, i.e., each thread processes $K \times L$ MBs in a tile sequentially, and different tiles are processed by different independent threads concurrently on the GPU.

Followed from the discussion in Section IV-A, individual MBs are not independent under smpUMHexagonS. In particular, macroblocks depend on their neighbors in the following ways:

First, to compute the rate term R in the Lagrangian cost the motion vectors of the neighboring MBs are required. If a neighboring MB belongs to another tile, we assume its motion vector equal to zero in computing R. Therefore, with tiling, the computed Lagrangian cost may not be very accurate, and suboptimal motion vectors may be chosen by smpUMHexagonS as a result. The impact of tiling in this case depends on the value of λ and hence the target bit-rate. For low bit-rate applications (rate constrained), encoders would focus more on rate efficiency, and large λ would be chosen and the rate

term would dominate the Lagrangian cost [48]. Tiling therefore shall have a more pronounced negative impact on the performance of smpUMHexagonS for low bit-rate applications (since tiling affects the rate term).

• Second, smpUMHexagonS (and many other fast ME [47]) uses motion vector prediction, i.e., motion vectors of the neighboring MBs are used to initialize the search. Under tiling, some information about neighboring motion vectors is not available, and this may result in poor-quality initial search points, and suboptimal motion vectors may get selected at the end of the search (hence the RD performance is compromised). Moreover, since smpUMHexagonS employs early termination, poor initial points may also result in longer processing time, as more search points would need to be examined until the cost is small enough to terminate the search (e.g., we observe about 4% increase in the ME processing time when encoding the HD 720P sequence *Harbour* using tiling K = 1, L = 1 in the sequential smpUMHexagonS).

The above discussions are also applicable to many other fast ME algorithms. Note that in our simulation tiling is used only in ME to facilitate GPU computation, and the rest of the encoding proceeds in the same manner as in the reference software. Therefore, our tiling is different from other partitioning ideas such as slice [47], where individual partitions are treated independently in most of the encoding.

Fig. 8. GPU-based fast motion estimation: the current frame is divided into multiple tiles to facilitate parallel processing in ME. Here each square represents a macroblock.

C. Experiments

To examine the performance of the GPU based fast ME using tiling, we conduct experiments on PCs equipped with one GeForce 8800 GTS PCIe graphics card with 96 stream processors [15], and an Intel Core 2 Quad Q9400 2.66 GHz CPU with 3.23 GB of RAM. We use NVIDIA CUDA [39] to implement the GPU code. We choose CUDA solely because of the availability of the NVIDIA device in our laboratory, and we remark that there are other well-designed GPU programming models such as ATI CTM [49], Stream Computing SDK and Brook+ [50].

We first evaluate how tiling may affect the RD performance. We use JM 14.2 to encode HD 720P sequences (1280×720 , 60 frame per second) *Crew*, *City*, *Harbour* and *Night* (We focus on encoding HD videos because of its high computational requirement, and because of the growing interest on HD contents). We use H.264 high profile with search range of 64. All the pictures are encoded as P-frames except the initial I-frame. Figure 9 depicts the RD performance with different tile sizes for the Harbour sequence. As shown in the figure the impact of tiling is small in this case until tile size is down to K = 1, L = 1, when the degradation is about 0.2 dB compared to the original reference software (with smpUMHexagonS). Table III shows the average PSNR degradation and the average increase in bit-rate using different tile sizes, measured by BDPSNR and BDBR respectively. Note that BDPSNR and BDBR are used frequently in the video standardization community [51]. The results suggest tiling may lead to average degradation between 0.08 dB to 0.4 dB for these sequences with tile size K = 1, L = 1.

We then discuss how tiling may affect the speedup. Table IV shows the GPU execution time (in integer-pel ME) with different tile sizes, and Figure 10 shows the speedup between the GPU implementation (with tiling and using parallel processing on multi-core) and the sequential CPU implementation (without tiling and using sequential processing on a single core). Comparison with parallel program code on multiple CPU cores will be discussed next. The GPU execution time includes the overhead to transfer the video frames from system memory to GPU memory. Compiler optimization is applied to both the GPU program and the CPU program. However, both the GPU/CPU code have rooms for further speed improvement. In particular, the GPU code stores pixel data in global memory (off-chip memory), which has considerable access latency [39]. As motion estimation is fairly memory access intensive (SAD calculation performs only three mathematical operations per two memory loads, giving an arithmetic intensity of 1.5, which is rather small for GPU computation [37]), such latency may impact the GPU code performance. Therefore, the code can be improved by judicious use of shared memory (on-chip memory) [37]. As shown in Figure 10 speedup increases with smaller tile size, as more independent threads can be scheduled. This is particularly important in the current GPU code to hide the memory access latency. Note also that different sequences have different GPU execution time and speedups, as different video contents may lead to different execution paths in smpUMHexagonS and different amount of penalty incurred by execution serialization. Figure 10 suggests speedups of 1.5 to 3.5 can be achieved in integer-pel smpUMHexagonS in these sequences using tile size K = 1, L = 1.

Figure 11 shows the speedup between the GPU implementation and a parallel CPU implementation using the four CPU cores on the Intel Core 2 Quad. To achieve parallel CPU processing, the current frame is partitioned into four tiles of equal number of MB rows (i.e., L=width of the video frame in MB, K=height of the video frame in MB / 4), and each tile is processed by an independent thread running on a CPU core. We use OpenMP to implement the parallel CPU program [52]. We observe the parallelization reduces the CPU running time by a factor of three approximately. Note that the theoretical maximum speedup of four cannot be achieved by this parallelization strategy, as smpUMHexagonS

Fig. 9. RD performance of *Harbour* with different tile sizes in fast motion estimation. Here "Original" refers to the reference software (that is, without tiling).

TABLE III

TRADEOFF BETWEEN TILE SIZE AND RD PERFORMANCE. AVERAGE INCREASE IN BIT-RATE AND AVERAGE PSNR DEGRADATION ARE COMPUTED WITH RESPECT TO THE REFERENCE SOFTWARE (THAT IS, WITHOUT TILING).

		Crew		City		Ha	Harbour		Night	
Tile	Number of	BDBR	BDPSNR	BDBR	BDPSNR	BDBR	BDPSNR	BDBR	BDPSNR	
size	tiles	(%)	(dB)	(%)	(dB)	(%)	(dB)	(%)	(dB)	
K = 1, L = 1	3600	3.135	-0.082	12.933	-0.407	5.578	-0.221	4.636	-0.17	
K = 1, L = 4	900	3.081	-0.079	11.115	-0.352	2.385	-0.094	3.546	-0.13	
K = 1, L = 16	225	3.116	-0.08	11.171	-0.35	2.246	-0.089	3.415	-0.125	
K = 1, L = 40	90	3.224	-0.083	10.821	-0.339	2.205	-0.087	3.4	-0.124	
K = 4, L = 80	12	0.63	-0.016	1.412	-0.044	0.57	-0.022	1.19	-0.043	
K = 16, L = 80	3	0.094	-0.003	0.261	-0.008	0.07	-0.003	0.161	-0.006	

may spend different execution time on each MB and optimal load balancing cannot be achieved by simple tiling. Figure 11 suggests the running time of the GPU implementation and the parallel CPU implementation can be comparable in some cases (while the GPU implementation incurs some RD performance degradation as depicted in Table III).

In the experiment, we observe the overhead to transfer a frame from CPU to GPU is about 1.6 ms, and this is about 0.1% to 0.2% of the running time of integer pel ME (see Table IV). In general, data transfer overhead could be a less serious issue in inter frame encoding compared with decoding and intra frame encoding, since inter frame encoding requires a significantly larger amount of execution time in general.

Finally, we would like to remark that both the CPU and GPU implementations can be further optimized. Our discussion has suggested that it is non-trivial to achieve the peak performance offered by these multi-core devices in video coding, and more algorithm research and instruction level optimization would be needed.

V. CONCLUSIONS AND DISCUSSION

We have reviewed previous work on using GPUs for video encoding and decoding. In particular, we have discussed how some video coding modules can be implemented in certain ways to expose as much data parallelism as possible, so that the massive parallel processing capability of GPUs can be fully utilized. Simulation results in previous work suggest GPUbased implementations can achieve considerable speedups for some of the most computation-intensive modules in video coding. Therefore, it could be a cost-effective approach to leverage the computing power of GPUs to meet the data processing requirement in video coding. We have also discussed an example to partition the video decoding flow between CPU and GPU to achieve maximum overlapping of computation. In addition, we have discussed a GPU based fast motion estimation and examined the tradeoff between speedup and rate-distortion performance.

There are several related research issues. First, there seems to be no study on partitioning the encoding flow between CPU and GPU. Second, with the availability of many different video formats (e.g., SD, HD) and coding standards there is a growing need to *transcode* one encoded video format to another [53]–[55]. However, while there are a few commercial transcoding applications available [56], [57], there seems to be no prior work on investigating the optimal usage of GPUs for transcoding. Note that unlike video encoding/decoding, there is no standard algorithm for video transcoding, and there are many previously proposed approaches which achieve a wide range of transcoding quality with different complexity requirements [53]. This complicates the study of GPU-based transcoding.

TABLE IV

GPU execution time for fast integer-pel motion estimation with different tile width (tile height K is equal to one). Data transfer overheads are included.

Tile	Number of	GPU execution time (ms)				
width	threads					
		Crew	City	Harbour	Night	
L = 1	3600	835.05	927.32	1248.95	1688.50	
L = 4	900	959.16	1005.55	1341.45	1975.95	
L = 16	225	2169.25	2108.71	2763.79	4175.44	
L = 40	90	4373.63	4165.28	5318.38	6920.73	

Fig. 10. Tradeoff between tile width and speedup (tile height K is equal to one). Speedup is the ratio of CPU running time (sequential program code on one CPU core) to GPU running time (including data transfer overhead).

ACKNOWLEDGMENT

This work has been supported in part by the Innovation and Technology Commission (project no GHP/048/08) and the Research Grants Council (project no. RPC07/08.EG22 and project no. 610109) of the Hong Kong Special Administrative Region, China. The authors would also like to thank the editor and the anonymous reviewers for their comments which helped improve the paper significantly.
